October 15, 2019

Version 1.0.4 - comments are welcome !

Abstract

This note discusses the estimation of the parameters of fixed-effects regression with a AR(1) perturbations. In the most general case of non-random fixed-effects model, it notably highlights that current estimation procedures (based on the Baltagi et Wu (1999) transformation) fails to take into account possible missingness of the data, with two main contributions. First, it shows the Baltagi et Wu (1999) transformation is not adapted in this most general case as soon as there are missing data, and proposes a novel transformation that ensures a consistent estimation of the β . Second, it highlights that the variance of the perturbations is also currently badly estimated, and proposes as well a method to correctly estimate it. MonteCarlo simulation illustrate the interest of these novel estimation methods in finite dimensions.

1 Introduction

This note considers the estimation of linear unobserved effects panel data models¹ with AR(1) disturbances, that refer to processes of the form:

$$y_{it} = x'_{it}\beta + \nu_i + u_{it} \quad (1)$$

$$u_{it} = \rho u_{it-1} + \varepsilon_{it} \quad (2)$$

where $|\rho| < 1$ and the ε_{it} 's are i.i.d. disturbances with mean 0 and variance σ_ε^2 .

Such estimations are common in the wage equation literature (with even higher order of correlation), and are not infrequent in the general economics literature. They are performed in Stata with the command *xtregar*, which has been used in influential and recent economics articles such as Dafny (2010), Hau *et al.* (2013) or Prieto et Lago-Peñas (2012).

In Cazenave-Lacroutz et Lin (2019), we proposed new estimators for the auto-correlation coefficient. In the particular case of random-effects model (that is: ν_i is exogenous to the covariables of the models) and a positive auto-correlation parameter,² it enables to have consistent or asymptotically consistent estimators for all parameters of the model when there are enough individuals with at least two consecutive observations and at least three observations.

We now turn to the more general case when no hypothesis is made regarding the exogeneity of the fixed effects. First we remind the properties of the current estimation method (for instance adopted by the Stata software **xtregar**, **fe**). Additionally, we explain why it works very well to estimate the variance of the perturbation in the balanced case, but fails to do so in the unbalanced case. We also propose a novel estimation method for the coefficients of the independent variable, as the current estimation method may fail in some instances. Second, a consistent estimator of the variance of the perturbations is proposed. Third, we illustrate the above assertions through MonteCarlo simulations that compare the respective performances of the

¹That is in both fixed and random effects models.

²In case of a negative auto-correlation parameter, asymptotically consistent estimator are provided, where the convergence is achieved when the minimum number of period per individual goes to infinity.

(more specific) random-effects estimators and of the (more general) fixed-effects estimators. We eventually conclude.

2 The current estimation method

In all the paper, we consider that a consistent estimator of the autocorrelation parameter ρ is known (Cazenave-Lacroutz et Lin, 2019). To alleviate the notations, we even consider that the true value of ρ is known.

When the fixed-effects are assumed to be exogeneous to the covariates (the random-effects model), Baltagi et Wu (1999) propose a transformation of the data that enables to get consistent estimates of the β parameter, of the variance of the fixed-effects, and of the variance of the perturbations.

In the general case (when there is no hypothesis regarding the exogeneity of the fixed-effects), the current estimation method (for instance implemented by the Stata command `xtregar`) first applies to the fixed-effects model the Baltagi-and-Wu transformation (Baltagi et Wu, 1999). We detail it below.

2.1 The current estimation method

Baltagi et Wu (1999) derive a transformation $C_i(\rho)$ of the data that removes the AR(1) component. Following this transformation, one gets:

$$\begin{aligned} y_{i,t_i,j}^* &= (1 - \rho^2)^{1/2} y_{i,t_i,j} \text{ if } j == 1 \\ &= (1 - \rho^2)^{1/2} \left(y_{i,t_i,j} \frac{1}{(1 - \rho^{2(t_{i,j} - t_{i,j-1})})^{1/2}} - y_{i,t_{i,j-1}} \frac{\rho^{t_{i,j} - t_{i,j-1}}}{(1 - \rho^{2(t_{i,j} - t_{i,j-1})})^{1/2}} \right) \text{ if } j > 1 \end{aligned} \quad (3)$$

Let us consider equation (1):

$$y_{it} = x'_{it}\beta + \nu_i + u_{it}$$

By applying the Baltagi-and-Wu transformation, one gets:

$$y_{it}^* = x_{it}^{*'}\beta + \nu_{i,t}^* + u_{it}^* \quad (4)$$

Quite importantly, note that the fixed effects ν_i have become $\nu_{i,t}^*$. In the general case, the Baltagi-transformed fixed effects are no longer fixed over time.³

It is easy to show that the error terms u_{it}^* are no longer correlated and homoskedastic.

The current estimation method (see Stata - xtregar / Methods and Formula) then differentiates this equation with the mean and grand mean. Let us note for a variable x , with $n_i = \sum_{t=1}^T 1(j_0/t_{i,j_0} == t)$:

$$\begin{aligned} \overline{x^*} &= \frac{\sum_{j=2}^{n_i} x_{i,t(i,j)}^*}{n_i - 1} \\ \overline{\overline{x^*}} &= \frac{\sum_{i=1}^N \sum_{j=2}^{n_i} x_{i,t(i,j)}^*}{\sum_{i=1}^N (n_i - 1)} \\ x_{it}^{**} &= x_{it}^* - \overline{x^*} + \overline{\overline{x^*}} \end{aligned} \quad (5)$$

The transformed equation is thus:

$$y_{it}^{**} = x_{it}^{**'}\beta + \nu_{it}^{**} + u_{it}^{**} \quad (6)$$

An OLS regression of y^{**} on the x^{**} and a constant is then performed.

2.2 The estimation of the β

It is trivial to see that the current methods enables to get consistent estimates of the β in the balanced case, as the $\nu_{i,t}$ are independent of t in this very particular case and are thus dropped due to the demeaning. This note makes no contribution to that regard.

In the unbalanced case, even if this method seems to provide consistent estimators of the β in many of our Monte-Carlo simulations, we are able to show its validity only under specific hypotheses (see Annex A). In Section 5, we also present a Monte

³The balanced case is an exception to that regard, as in this very particular case: $\nu_i^* = (1 - \rho)\nu_i$

Carlo simulation where β does not seem to be consistently estimated.

Happily, we are able to propose a novel (consistent) estimation of the β in Section 3.

In addition, note that there is no reason in the above methods that the identified constant respects the usual convention⁴ that the sum of the ν_i is equal to zero.

2.3 An imprecise estimation of the fixed effects ν_i :

As such, the current estimation method (as well as the estimation method suggested above) enables also to estimate (although there are not centered around zero):

$$\hat{\nu}_i = y_{i,t}^* - (x'_{i,t}\hat{\beta})^* \quad (7)$$

There might be made centered around zero. Even without centering it, the variance of these estimates provides an estimate of the variance of the fixed-effects. As such variance is based on the imprecise estimates of the individual fixed-effects, it is quite imprecise. It converges however towards the true variance when the minimal number of observation per individual tends to infinity.

2.4 The estimation of the variance of the perturbations

We focus here on the current estimation of the variance of the perturbations σ_η . The current estimation method takes as an estimator of σ_η the empirical variance of $u_{i,t}^*$. In the unbalanced case, there is no reason why it would yield a consistent estimator of σ_η . Monte Carlo simulations in Section 5 clearly shows that the corresponding estimates can be far away from the true value of σ_η .

It however avers that in the balanced case, it yields a consistent estimator of σ_η . We show below why it is the case

The balanced case:

By applying the Baltagi-and-Wu transformation to the balanced case to the pertur-

⁴This convention is usual in Stata.

bation $u_{i,t}$, it comes:

$$\begin{aligned} u_{i,t}^* &= (1 - \rho^2)^{1/2} \text{ if } t_{i,j} == 1 \\ &= (1 - \rho^2)^{1/2} \left(u_{i,t} \frac{1}{(1 - \rho^2)^{1/2}} - u_{i,t-1} \frac{\rho}{(1 - \rho^2)^{1/2}} \right) \text{ if } t_{i,j} > 1 \end{aligned}$$

We remind equation (2).

$$u_{i,t} = \rho u_{i,t-1} + \varepsilon_{it}$$

This enables to conclude as we easily get that:

$$u_{i,t}^* = \eta_{i,t}$$

3 A consistent estimator of the β

We propose a modification of the Baltagi-and-Wu transformation that yields a consistent estimator of the β coefficient.

We observe that:

$$y_{it}^* = x_{it}^{*'} \beta + (1 - \rho^2)^{1/2} 1_{i,t} \nu_i + u_{it}^*$$

Where:

$$\begin{aligned} 1_{i,t_{i,j}} &= 1 \text{ if } j == 1 \\ &= \frac{1 - \rho^{t_{i,j} - t_{i,j-1}}}{(1 - \rho^{2(t_{i,j} - t_{i,j-1})})^{1/2}} \text{ if } j > 1 \end{aligned} \quad (8)$$

We propose thus the following transformation that make the transformed fixed-effects to remain fixed over time, and the transformed perturbation to be uncorrelated:

$$x_{it}^{*2} = \frac{1}{1_{i,t}} x_{it}^* \quad (9)$$

Hence, in the general case of the fixed-effect models, **we rather use the following transformation rather than the Baltagi-and-Wu transformation:**

$$\begin{aligned} x_{i,t_{i,j}}^{*2} &= (1 - \rho^2)^{1/2} x_{i,t_{i,j}} \text{ if } j == 1 \\ &= (1 - \rho^2)^{1/2} \left(x_{i,t_{i,j}} \frac{1}{(1 - \rho^{(t_{i,j} - t_{i,j-1})})} - x_{i,t_{i,j-1}} \frac{\rho^{t_{i,j} - t_{i,j-1}}}{(1 - \rho^{(t_{i,j} - t_{i,j-1})})} \right) \text{ if } j > 1 \end{aligned} \quad (10)$$

From that point on, the principle is the following: by demeaning as in the current

method, we get rid of all the terms with ν_i :

$$y_{it}^{*2} - \bar{y}_{it}^{*2} = (x_{it}^{*2'} - \bar{x}_{it}^{*2'})\beta + (u_{it}^{*2} - \bar{u}_{it}^{*2})$$

An OLS estimation of the above regression yields a consistent estimate of β .

In practice, we use the Stata **xtreg, fe vce(robust)** command, as the errors following transformation (10) are heteroscedastic and that demeaning get rid of the fixed-effects but introduce correlation between the residuals. The above Stata command take into account the note of Stock et Watson (2008) that tackles both issues.⁵

4 A new estimator of the variance of the perturbations

A naive estimator of σ_ε^2 can be obtained by explicitly computing $\hat{u}_{i,t} := y_{i,t} - x'_{i,t}\hat{\beta} - \hat{\nu}_i$; considering its empirical variance, and multiplying it by $1 - \rho^2$ to obtain an estimator σ_ε^2 . It however yields an imprecise estimator of σ_ε , as it relies on the imprecise estimation of the ν_i . We therefore propose an estimator that is not based on the estimation of the ν_i .

To do so, we define:

$$\tilde{y}_{i,t} = y_{i,t} - x'_{i,t}\beta \quad (11)$$

As highlighted above, under the missing-at-random hypothesis, the current estimation method enables to get a consistent estimate of β , and thus to compute a consistent estimate of the above quantity.

We observe that:

$$\tilde{y}_{i,t} = y_{i,t} - x'_{i,t}\beta = \nu_i + u_{i,t} \quad (12)$$

We define :

$$\tilde{\tilde{y}}_{i,t(i,j)} = \tilde{y}_{i,t(i,j)} - \tilde{y}_{i,t(i,j-1)} = u_{i,t(i,j)} - u_{i,t(i,j-1)} \quad (13)$$

⁵Note that the variance-covariance matrix is a diagonal matrix whose coefficients are $\frac{\sigma_\varepsilon}{1_{i,t}^2}$. As it is explicitly known, a even more efficient estimator that takes into account this explicit form is possible. This is let to further work.

By successively applying equation (2), it comes:

$$\widetilde{y}_{i,t(i,j)} = (\rho^{t(i,j)-t(i,j-1)} - 1)u_{i,t(i,j-1)} + \sum_{k=0}^{t(i,j)-t(i,j-1)-1} \rho^k \varepsilon_{i,t(i,j)-k} \quad (14)$$

Hence, since all the above terms in the sum are uncorrelated and of mean 0:

$$E(\widetilde{y}_{i,t(i,j)}^2) = \text{Var}(\widetilde{y}_{i,t(i,j)}) = (1 - \rho^{t(i,j)-t(i,j-1)})^2 \sigma_u^2 + \sum_{k=0}^{t(i,j)-t(i,j-1)-1} \rho^{2k} \sigma_\varepsilon^2$$

Thus:

$$\sigma_\varepsilon^2 = \frac{E(\widetilde{y}_{i,t(i,j)}^2)}{\frac{(1-\rho^{t(i,j)-t(i,j-1)})^2}{(1-\rho^2)} + \frac{(1-\rho^{2(t(i,j)-t(i,j-1))})}{(1-\rho^2)}} \quad (15)$$

We have obtained:

$$\sigma_\varepsilon^2 = E(w_{i,t}) \quad (16)$$

where:

$$w_{i,t} = \frac{\widetilde{y}_{i,t(i,j)}^2}{\frac{(1-\rho^{t(i,j)-t(i,j-1)})^2}{(1-\rho^2)} + \frac{(1-\rho^{2(t(i,j)-t(i,j-1))})}{(1-\rho^2)}} \quad (17)$$

Denoting $\hat{w}_{i,t}$ a estimate of $w_{i,t}$, one gets a natural consistent estimate of σ_ε^2 :

$$\hat{\sigma}_\varepsilon^2 = \frac{1}{N} \sum_{i=1}^N \hat{w}_{i,t} \quad (18)$$

5 Monte Carlo simulations

To illustrate the above theoretical part, we consider Monte Carlo simulations with the following basis parameters $N = 500$; $T = 10$; $\rho = 0.6$; $\sigma_\varepsilon = 0.3$; $\sigma_\nu = 0.35$. Those parameters are already used by Cazenave-Lacroutz et Lin (2019), enabling comparability. ⁶

⁶The values of ρ , σ_ε and σ_ν were chosen by Cazenave-Lacroutz et Lin (2019), as they were typical of what they encountered in an applied study, see Cazenave-Lacroutz *et al.* (2019). $T = 10$ and $N = 500$ make consider a panel that is short in the time dimension but with an number of individual close to infinity.

5.1 In the random-effect design

First, we consider cases where the fixed effects ν_i are exogeneous from the covariables x .⁷ This is a very particular case, where a random-effects model can also be applied. This allows us to compare the estimation advantages of making the assumption of a random-effects model (when suitable) rather than the more general fixed-effects model.

With our estimation method for σ_ϵ , both the fixed-effects model and the random-effects model are able to provide a correct estimation of the variance of the perturbations (see Table 1). However, due to the limited number of periods observed per individual, the estimation of the variance of the fixed effects σ_ν is biased in the fixed-effects model, but unbiased in the random-effect models.⁸

We also note that in this particular case, the coefficient of the covariable is consistently estimated by all estimation methods.

In Table 2, we consider the same simulations, but we increase the number of period to $T = 100$ (rather than $T = 10$). Accordingly with our above interpretations, this yields estimates of the variance of the fixed-effects σ_ν that are no longer significantly different from its true value in the general case of the fixed-effects model.

⁷Typically, we consider as covariables a random draw that has an additive impact on the dependent variable, and a constant.

⁸Indeed, in the random-effects model, it can be estimated without relying on the imprecise estimation of the various ν_i .

Legend: The average estimators should not be significantly different from the true values. It is the case only for those in bold. Significance levels for the differences with the true values are otherwise pinpointed by stars: * ($p < 0.10$), ** ($p < 0.05$), *** ($p < 0.01$)

Note 1: Approximately half of a panel of 500 individuals observed each over T = 100 periods has been randomly deleted, before the Monte Carlo process has been implemented with 50 replications.

The estimates of σ_ε and of σ_ν in the two last lines are obtained by estimating first ρ_{BFN} (or ρ_{BFN2U}), and then by imposing it as the estimate of ρ in *xtregar*.

5.2 In the general case

We implement two changes in regard with the simulations presented in Table 1.

First, we do not consider any longer the specific case when the fixed effects are exogeneous to the covariates.⁹ Hence, we no longer present the random-effects model, as it is based on this hypothesis.

Second, while the data were missing at random, we deviate from this missing pattern. In the "Non missing at random", missingness is based on the value taken by the covariable of the model. As shown in Table 3, this yields a coefficient for the covariable that is significantly different from its true value, which is not observed in the Missing-at-random case. We do not know if this is because the Missing-at-random hypothesis was not respected. Our purpose is mainly to show that the β are not always consistently estimated with the current procedure. As expected, our corrected procedure yields a consistent estimate in both studied case.

⁹More precisely, the covariate is the sum of a random term and the fixed-effect.

Table 3. Monte Carlo simulations on an unbalanced panel, T=10, general case

	Missing-at-random				Non missing-at-random			
	ρ	σ_ε	σ_ν	covar	ρ	σ_ε	σ_ν	covar
true values	0.6	0.3	0.35	3	0.6	0.3	0.35	3
with true ρ and xtregar	.6 (0)	.621*** (4.9e-03)	.442*** (.019)	3 (.012)	.6 (0)	.458*** (.017)	.377 (.021)	2.95*** (.013)
with true ρ and corrected xtregar	.6 (0)	.301 (3.5e-03)	.447*** (.016)	3 (6.7e-03)	.6 (0)	.301 (4.4e-03)	.355 (.018)	3 (8.0e-03)
with ρ_{BFN} and corrected xtregar	.581 (.04)	.299 (3.0e-03)	.447*** (.016)	3 (6.5e-03)	.581 (.04)	.3 (5.4e-03)	.355 (.018)	3 (8.0e-03)

Legend: The average estimators should not be significantly different from the true values. It is the case only for those in bold. Significance levels for the differences with the true values are otherwise pinpointed by stars: * ($p < 0.10$), ** ($p < 0.05$), *** ($p < 0.01$)

Note 1: Approximately half of a panel of 500 individuals observed each over $T = 10$ periods has been randomly deleted, before the Monte Carlo process has been implemented with 50 replications.

The estimates of σ_ε and of σ_ν in the two last lines are obtained by estimating first ρ_{BFN} (or ρ_{BFN2U}), and then by imposing it as the estimate of ρ in *xtregar*.

Note 2: *covar* is an independent variable that is the sum of a random term and the fixed-effect.

6 Conclusion

Whereas Baltagi et Wu (1999) proposed a way of consistently estimating the parameters of a random-effects regression with AR(1) perturbations¹⁰, to the best of our knowledge, no previous paper attempted to generalize their method to the case where no hypothesis is made regarding the exogeneity of the fixed effects. Current practice consisted in applying the Baltagi-and-Wu transformation before demeaning. We show that this procedure is adapted in the very particular case of balanced panels, but not necessarily in the more common case of unbalanced panel.

In the unbalanced case, we provide Monte-Carlo simulations where the current procedure does not yield a consistent estimation of the β parameter. Furthermore, we propose a novel transformation that enables to get such consistent estimates also in the unbalanced case. We also notice that the constant does not *a priori* respects the convention that it makes the mean of the fixed effects null, but the constant is usually not an object of interest *per se*. More importantly for some applications (e.g. for simulations following the estimation), the variance of the perturbation was not correctly estimated. In case a consistent estimate of β is available, we propose an additional estimation procedure that enables to get a consistent estimator of σ_ϵ . Hence, all parameters of this type of model are thus consistently estimated.¹¹

Annexes

A Consistency of $\hat{\beta}$

We focus on the consistency of $\hat{\beta}$, where $\hat{\beta}$ denotes the OLS estimator of β obtained from equation (6). It suffices to show that the orthogonality condition $\mathbb{E}(x_{it_{ij}}^{**}(\nu_{it_{ij}}^{**} + u_{it_{ij}}^{**})) = 0$ holds. First, the relation $\mathbb{E}(x_{it_{ij}}^{**} u_{it_{ij}}^{**}) = 0$ trivially follows from the strict exogeneity assumptions $\mathbb{E}(x_{it_{ij}} u_{kt_{kl}}) = 0$. According to Lemma 1, the second relation $\mathbb{E}(x_{it_{ij}}^{**} \nu_{it_{ij}}^{**}) = 0$ holds if one of two conditions holds.

Lemma 1: Condition $\mathbb{E}(x_{it_{ij}}^{**} \nu_{it_{ij}}^{**}) = 0$ holds for all $2 \leq j \leq n_i$ if:

$$\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} = \left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}} \quad (19)$$

for all $2 \leq j \leq n_i$.

or if:

$$\mathbb{E}(x_{it_{ij}}^{**} \nu_i) = 0 \quad (20)$$

First, we compute

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^{**} \nu_{it_{ij}}^*) &= \mathbb{E}(x_{it_{ij}}^{**} \sqrt{1 - \rho^2} \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} \nu_i) \\ &= \sqrt{1 - \rho^2} \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} \mathbb{E}(x_{it_{ij}}^{**} \nu_i),\end{aligned}$$

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^{**} \overline{\nu_i^*}) &= \mathbb{E}(\frac{1}{n_i - 1} \sum_{l=2}^{n_i} x_{it_{ij}}^{**} \nu_{it_{il}}^*) \\ &= \mathbb{E}(\frac{1}{n_i - 1} \sum_{l=2}^{n_i} \sqrt{1 - \rho^2} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}} x_{it_{ij}}^{**} \nu_i) \\ &= \frac{\sqrt{1 - \rho^2}}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}} \mathbb{E}(x_{it_{ij}}^{**} \nu_i)\end{aligned}$$

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^{**} \overline{\nu^*}) &= \frac{1}{\sum_{l=1}^N (n_l - 1)} \mathbb{E}(\sum_{l=1}^N \sum_{k=2}^{n_l} x_{it_{ij}}^{**} \nu_{lt_{lk}}^*) \\ &= \frac{1}{\sum_{l=1}^N (n_l - 1)} \mathbb{E}(\sum_{k=2}^{n_i} x_{it_{ij}}^{**} \nu_{it_{ik}}^*) \\ &= \frac{n_i - 1}{\sum_{l=1}^N (n_l - 1)} \mathbb{E}(x_{it_{ij}}^{**} \overline{\nu_i^*}),\end{aligned}$$

the second equality following from the independency between $x_{it_{ij}}^{**}$ and $\nu_{lt_{lk}}^*$ for $l \neq i$, which yields $\mathbb{E}(x_{it_{ij}}^{**} \nu_{lt_{lk}}^*) = \mathbb{E}(x_{it_{ij}}^{**}) \mathbb{E}(\nu_{lt_{lk}}^*) = 0$.

Since $\nu_{it_{ij}}^{**} = \nu_{it_{ij}}^* - \overline{\nu_i^*} + \overline{\nu^*}$, we have:

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^{**} \nu_{it_{ij}}^{**}) &= \mathbb{E}(x_{it_{ij}}^{**} (\nu_{it_{ij}}^* - \overline{\nu_i^*} + \overline{\nu^*})) \\ &= \sqrt{1 - \rho^2} \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} \mathbb{E}(x_{it_{ij}}^{**} \nu_i) - (1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}) \mathbb{E}(x_{it_{ij}}^{**} \overline{\nu_i^*}) \\ &= \sqrt{1 - \rho^2} \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} \mathbb{E}(x_{it_{ij}}^{**} \nu_i) - (1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}) \frac{\sqrt{1 - \rho^2}}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}} \mathbb{E}(x_{it_{ij}}^{**} \nu_i)\end{aligned}$$

Hence $\mathbb{E}(x_{it_{ij}}^{**} \nu_{it_{ij}}^{**}) = 0$ if and only if condition (19) holds or $\mathbb{E}(x_{it_{ij}}^{**} \nu_i) = 0$. This demonstrates Lemma 1.

We first consider equation (19). It writes:

$$\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}} = \left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}}$$

for all $2 \leq j \leq n_i$.

If these conditions were true, the quantities $\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}$, $2 \leq j \leq n_i$, would all be equal.

In the very particular case of the balanced case, all these conditions would be summed up in one single condition:

$$1 = 1 - \frac{1}{N}$$

It approximately holds for large N .

Hence, if we are in a balanced panel, these conditions are approximately respected.

Note that in the unbalanced case, if the data pattern were random, then condition (19) would be valid in expectancy (and for N large enough).

Lemma 2: Under the hypothesis that missing occurs independently of the observable $x_{i,t}$ and of the fixed-effects ν_i (i.e. the *missing-at-random* hypothesis), equation (19) holds in expectancy for N large enough.

We compute

$$\begin{aligned}
& \mathbb{E}\left(\left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}}\right| n_1, \dots, n_N) \\
&= \left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} \sum_{l=2}^{n_i} \mathbb{E}\left(\frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}}\right| n_1, \dots, n_N) \\
&= \left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} (n_i - 1) \mathbb{E}\left(\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right| n_1, \dots, n_N) \\
&= \left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \mathbb{E}\left(\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right| n_1, \dots, n_N) \\
&= \mathbb{E}\left(\left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right| n_1, \dots, n_N)
\end{aligned}$$

the second equality following from the fair assumption that $\mathbb{E}\left(\frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}}\right| n_i)$ does not depend on l . Taking expectations, we have

$$\begin{aligned}
& \mathbb{E}\left(\left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1}{n_i - 1} \sum_{l=2}^{n_i} \frac{1 - \rho^{t_{il} - t_{il-1}}}{\sqrt{1 - \rho^{2(t_{il} - t_{il-1})}}}\right) \\
&= \mathbb{E}\left(\left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right)
\end{aligned}$$

Then, condition 19 holds in expectancy if and only if

$$\mathbb{E}\left(\frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right) = \mathbb{E}\left(\left(1 - \frac{n_i - 1}{\sum_{i=1}^N (n_i - 1)}\right) \frac{1 - \rho^{t_{ij} - t_{ij-1}}}{\sqrt{1 - \rho^{2(t_{ij} - t_{ij-1})}}}\right)$$

which is the case when N grows to infinity.

We focus here on the condition $\mathbb{E}(x_{it_{ij}}^{}\nu_i) = 0$.**

First, we compute

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^*\nu_i) &= \frac{\sqrt{1-\rho^2}}{\sqrt{1-\rho^{2(t_{ij}-t_{ij-1})}}}\mathbb{E}((x_{it_{ij}} - \rho^{t_{il}-t_{il-1}}x_{it_{ij-1}})\nu_i) \\ \mathbb{E}(\overline{x_i^*}\nu_i) &= \frac{\sqrt{1-\rho^2}}{n_i-1} \sum_{j=2}^{n_i} \mathbb{E}\left(\frac{x_{it_{ij}} - \rho^{t_{il}-t_{il-1}}x_{it_{ij-1}}}{\sqrt{1-\rho^{2(t_{ij}-t_{ij-1})}}}\nu_i\right) \\ \mathbb{E}(\overline{\overline{x^*}}\nu_i) &= \frac{n_i-1}{\sum_{l=1}^N(n_l-1)}\mathbb{E}(\overline{x_i^*}\nu_i)\end{aligned}$$

Hence

$$\begin{aligned}\mathbb{E}(x_{it_{ij}}^{**}\nu_i) &= \mathbb{E}((x_{it_{ij}}^* - \overline{x_i^*} + \overline{\overline{x^*}})\nu_i) \\ &= \frac{\sqrt{1-\rho^2}}{\sqrt{1-\rho^{2(t_{ij}-t_{ij-1})}}}\mathbb{E}((x_{it_{ij}} - \rho^{t_{il}-t_{il-1}}x_{it_{ij-1}})\nu_i) - \left(1 - \frac{n_i-1}{\sum_{l=1}^N(n_l-1)}\right)\mathbb{E}(\overline{x_i^*}\nu_i) \\ &= \frac{\sqrt{1-\rho^2}}{\sqrt{1-\rho^{2(t_{ij}-t_{ij-1})}}}\mathbb{E}((x_{it_{ij}} - \rho^{t_{il}-t_{il-1}}x_{it_{ij-1}})\nu_i) \\ &\quad - \left(1 - \frac{n_i-1}{\sum_{l=1}^N(n_l-1)}\right)\frac{\sqrt{1-\rho^2}}{n_i-1} \sum_{j=2}^{n_i} \mathbb{E}\left(\frac{x_{it_{ij}} - \rho^{t_{il}-t_{il-1}}x_{it_{ij-1}}}{\sqrt{1-\rho^{2(t_{ij}-t_{ij-1})}}}\nu_i\right)\end{aligned}$$

A sufficient condition for $\mathbb{E}(x_{it_{ij}}^{**}\nu_i) = 0$ is that $\mathbb{E}(x_{it_{ij}}^*\nu_i)$ does not depend on j . Indeed, in this case,

$$\mathbb{E}(x_{it_{ij}}^{**}\nu_i) = \frac{n_i-1}{\sum_{l=1}^N(n_l-1)}\mathbb{E}(x_{it_{ij}}^*\nu_i),$$

which converges to 0 when N tends to infinity.

Note however that the necessary hypothesis for this result ($(x_{it_{ij}}^*\nu_i)$ does not depend on j) depends on the value of ρ (through the Baltagi-and-Wu transformation) and is thus not necessarily very general.
